Abstract

Gadolinium-based contrast agents (GBCAs) have provided much needed image enhancement in magnetic resonance imaging (MRI) important in advancement of disease diagnosis and treatment. The paramagnetic properties of ionized gadolinium have facilitated these advancements, but ionized gadolinium carries toxicity risk. GBCAs were formulated with organic chelates designed to reduce these toxicity risks from unbound gadolinium ions. They were preferred over iodinated contrast used in computed tomography and considered safe for use. As their use expanded, the development of new diseases associated with their use (including nephrogenic systemic fibrosis) have drawn more attention and ultimately caution with their clinical administration in those with impaired renal function. Use of GBCAs in those with preserved renal function was considered to be safe. However, in this new era with emerging clinical and experimental evidence of brain gadolinium deposition in those with repeated exposure, these safety assumptions are once again brought into question. This review article aims to add new perspectives in thinking about the role GBCA in current clinical use. The new information begs for further discussion and consideration of the risk/benefit ratio of use of GBCAs.

Introduction

Magnetic resonance imaging (MRI) serves as an important imaging technique necessary for disease diagnosis and treatment. Use of gadolinium-based contrast agents (GBCA) for MRI enhancement is useful in some instances and has been considered safe in most cases. Gadolinium is currently the only heavy metal suitable for MRI enhancement.
Properties of Gadolinium and Classification of Gadolinium-based Contrast Agents

Gadolinium (Gd) is a rare earth metal of the lanthanide series valued for its strong paramagnetic properties important for MRI enhancement. It is a heavy metal that forms $3^+$ charge with 7 unpaired electrons. These unpaired electrons attract nearby protons such as in water. Gd$^{3+}$ complexation reduces the relaxation time of nearby protons in a magnetic field at low concentrations to provide enhanced image quality important for tissue differentiation in disease diagnosis (1). Gadolinium is not part of the normal composition of human tissue like the trace element manganese (2), but was preferred for MRI enhancement due to its strong paramagnetic retention. Manganese can lose its paramagnetic properties through oxidation and can be retained in the liver with toxic potential. Animal studies discussed below showed that ionized gadolinium is toxic and must be chelated by a ligand for clinical use. These observations led to the development of modern GBCAs which contain linear or macrocyclic organic ligands to encapsulate the ion and reduce its toxicity.

Gadolinium-based contrast agents are divided into linear and macrocyclic categories based on the shape of the organic ligand. Linear agents are further divided into ionic and nonionic groups and included agents such as gadopentetate dimeglumine, gadodiamide, and gadoversetamide (3). Macroyclic agents contain organic rings complexed with Gd$^{3+}$ centrally and included agents such as gadoterate meglumine, gadobutrol, and gadoteridol (3). To date, there are 8 agents approved by the US Food and Drug Administration for MRI use (4). The American College of Radiology further
divides them into group I, group II and group III agents in Table 1 (5). The recommended human dose is 0.1 mmol/kg (6).

These GBCAs were considered more stable than gadolinium chloride with lower risk of Gd$^{3+}$ dissociation as reflected by a thermodynamic stability constant. This constant is determined by the rate at which ionized gadolinium dissociates from the ligand in vitro at a pH of 1. GBCAs with higher thermodynamic stability constants were considered more stable despite their derivation under non-physiologic conditions.

These agents were considered to be safe for intravenous (IV) use and were preferred to iodinated IV contrast used in computed tomography which carried risk of nephrotoxicity. The biodistribution was assumed to be extracellular (volume of distribution in intravascular and interstitial spaces) with little intracellular distribution apart from liver in some cases (3). In addition, they have limited protein binding, making their blood elimination quick with a short terminal half-life of 1.5 hours in those with normal renal function. Therefore, elimination of GBCAs is dependent on renal function and their retention is higher with impaired kidney function (7). GBCAs were considered safe for use in those with normal renal function, but this assumption was challenged with development of a new diseases observed after GBCA exposure.

**Early Experience with Gadolinium Compounds**

Humans were initially exposed to gadolinium from industrial use and later through the intravenous administration of gadolinium-based contrast agents (GBCA) for MRI in the 1980s. The free gadolinium ion is toxic and must be complexed with an organic ligand to improve its tolerance for in vivo administration. The toxicity of ionized gadolinium was
demonstrated *in vivo* by Abel and Talbot in their experiment using inhaled gadolinium oxide in male and female guinea pigs for periods of 40, 80 and 120 days. The lungs of guinea pigs exposed to inhaled gadolinium oxide “had less elastance than lungs from unexposed guinea pigs” with histological changes including “alveolar cell hypertrophy, septal wall thickening, lymphoid hyperplasia and macrophage proliferation” (8). It was also noted that the severity of the lesions increased as exposure time increased.

Intravenous gadolinium chloride (GdCl₃) led to toxic histologic, hematologic and plasma chemistry changes in male and female Sprague-Dawley rats when administered in various doses (0.07, 0.14 and 0.35 mmol/kg) by Spencer et al (9). At 48 hours post dose, hematologic changes included elevated white cell count in both sexes, elevated monocytes in males, decreased platelet numbers in males, prolonged activated partial thromboplastin time (APTT) in both sexes. Other plasma chemistry changes included elevated alkaline phosphatase, lactate dehydrogenase, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) in males. Histological changes included hepatocellular necrosis with hemorrhage around the portal tracts and enlarged Kupffer cells containing pale basophilic material in male rats. These hepatic changes evolved into multifocal chronic inflammation in all dose groups 14 days after administration. The same pale basophilic mineral deposits seen in Kupffer cells were also observed in the capillaries throughout the kidney in all rats receiving 0.14 and 0.35 mmol/kg GdCl₃ dosing. Multifocal necrosis of the proximal convoluted tubule was also present in female rats.

Ionized gadolinium toxicity is not unique since other rare earth metals in the lanthanide group also exhibited toxic effects in animals as summarized by Hirano and Suzuki (10).
Potential Toxic Effects of Gadolinium-based Contrast Agents

Nephrogenic Systemic Fibrosis

The first case of a new fibrosing dermopathy distinct from scleroderma was reported in 1997. This condition was named nephrogenic systemic fibrosis (NSF) and presents with cutaneous thickening or indurated and discolored skin affecting the limbs and trunk but sparing the face (11, 12). Skin lesion histology demonstrate dermal thickening and increased collagen bundle into the superficial fascia (11). Multiorgan involvement with internal organ fibrosis has been described leading to high mortality from death (11). NSF was recognized as distinct from systemic sclerosis, scleromyxoedema, and eosinophilic vasculitis due to negative anti-centromere and anti-scl70 antibodies. Over 400 cases of NSF have been reported since 1997. The severity of illness, time to disease manifestation and GBCA dosing exposure varies individually.

Collidge et al in 2007 noted the association between GBCA exposure and development of NSF in those with established renal failure in their retrospective analysis of local imaging data. Gadodiamide, a non-ionic linear agent, was used in most NSF cases in this study with a positive association between cumulative dose and dosing events. This association between NSF after GBCA exposure in those with renal impairment was echoed by others throughout the years as more clinical experience accumulated. NSF-like lesions were observed in rats exposed to gadodiamide in a preclinical study by Sieber et al (13).

The pathogenesis of NSF development remains poorly understood. Theories include prolonged GBCA retention due to renal impairment led to the release of free
gadolinium with tissue gadolinium deposition, ultimately triggering fibrosis (Figure 1). Kuo argues that inorganic gadolinium in the body does not trigger NSF nor does it maintain disease activity, but rather other key risk factors such as infection and inflammation should be considered (14). The mechanism of NSF is yet to be determined.

NSF was associated with exposure to many brands of GBCA despite claims of low likelihood based on thermodynamic stability. Gadobutrol, an agent considered with lowest risk potential for NSF, was associated with NSF. Endrikat et al advised caution in use of gadobutrol in those with chronic kidney disease stage 4 or 5 in their systematic review (15).

The association of NSF with GBCA exposure in renal impairment led to avoidance of these agents in those with low renal function or on dialysis. GBCA use in those without renal impairment was considered safe with more than 300 million doses administered to date since their introduction in the 1980s. It should be noted that renal impairment was defined based on estimated GFR as stated by the American College of Radiology Manual on Contrast Media (5). However, recent findings of gadolinium brain deposition have brought these assumptions under question.

**Gadolinium Deposition Disease**

Kanda et al discovered high signal intensity of both the dentate nucleus and globus pallidus on unenhanced T1-weighted magnetic resonance images in 19 patients who had received at least 6 doses of linear GBCAs compared to 16 patients who had MRI without GBCAs (16). The retrospective study revealed a dose relationship between high-signal intensity with a history of GBCA administration independent of renal
function. No specific GBCA was implicated as these patients had multiple exposures at different facilities, limiting comprehensive record review. Other retrospective studies confirmed these findings in those with multiple sclerosis and meningioma who received multiple GBCA administrations with prior MRI (17). Post-mortem studies confirmed that T1 shortening on MRI is probably due to gadolinium deposition (17, 18). Nehra et al demonstrated gadolinium accumulation within the cerebrospinal fluid of patients who received the macrocyclic GBCA gadobutrol (19). McDonald et al showed gadolinium deposition in human brain tissues of adults who had received gadodiamide for MRI without intracranial abnormalities on post-mortem examination (20). They also performed animal studies and showed that gadolinium tissue deposition in rats was 2 to 4-fold higher in following administration of linear agents gadodiamide and gadopentate dimeglumine compared with macrocyclic agents gadobutrol and gadoteridol (21). Gadolinium has also been observed with macrocyclic agents with the extent of deposition varying between agents (22). The severity of illness and time to disease manifestation varies individually.

These new findings led to cautionary statements by world health organizations including the American College of Radiology, Health Canada, the Canadian Association of Radiologists, the Australian Department of Health, the European Medicines Agency, the New Zealand Medicines and Medical Devices Authority and the Japanese Pharmaceuticals and Medical Devices Agency (23-29). The US Food and Drug Administration urged further patient education for those receiving GBCAs and for health care professionals to consider retention characteristics when choosing GBCAs for patients at higher risk for gadolinium retention (4). In addition, the FDA also required
GBCA manufacturers to conduct additional human and animal studies to assess the safety of these agents (4). The National Institutes of Health (NIH) urged the use GBCAs only when clinically indicated, to consider FDA label indications and dosing schemes, to use macrocyclic GBCAs in lieu of linear GBCAs if indicated, and encouraged intra- and interdepartmental research programs to evaluate T1 shortening in the brain and other organs of those patients who received multiple doses of GBCAs (17).

Tissue gadolinium deposition was found in preclinical studies with rats exposed to gadolinium chloride preceding the above human findings. When NSF was discovered, many investigative groups replicated this condition in animal models to study it further. Our research group observed negative biological effects of GBCA exposure in cell culture with increased expression of pro-fibrotic proteins such as alpha-smooth muscle actin and fibronectin (30). We replicated NSF in both rat and mice showing dermal histopathologic changes mirroring those observed in human NSF skin (7). We also observed gadolinium deposition in multiple organs including skin, kidney and heart and found evidence of bone marrow-derived fibrocytes in these tissues (31, 32). Myeloid C-C chemokine receptor 2 appeared to play an important role in fibrosis triggered by GBCA exposure (33, 34). Furthermore, our animal studies uncovered metabolic disruptions caused by GBCA exposure (35).

**Nephrotoxicity of Gadolinium-based Contrast Agents**

Gadolinium-based contrast agents have been preferred for image enhancement over IV iodinated contrast because of assumed lower potential to cause contrast-induced nephrotoxicity (CIN). These assumptions were based on their lower viscosity
and the lower dose of use (6). Naito et al conducted a prospective, randomized human study comparing contrast-induced nephrotoxicity (CIN) between gadodiamide and gadopentetate in 694 patients with chronic kidney disease stage 1 through 3 (36). Using cystatin-C as a biomarker of early stages of CIN since it tends to rise before serum creatinine, they found that gadodiamide exposure led to increases in cystatin-C in patients with CKD stage 1. In addition, gadodiamide exposure reduced creatinine clearance in patients with CKD stage 2. These changes were not observed with gadopentetate. These findings suggested “that gadodiamide has slight, but clinically unimportant, nephrotoxicity in subgroups of patients with CKD”. The study was limited by single measurement of serum creatinine levels and confounders for acute kidney injury such as congestive heart failure and concomitant nephrotoxic drug administration, rendering its conclusions about the safety of gadopentetate weak. The potential for CIN remains unclear in GBCA administration, especially in those with multiple lifetime exposures.

Experimentally, we observed renal glomerular changes with presence of lipid-like droplets and electron densities in mice exposed to GBCA (Figure 2). Proximal tubules demonstrate lipid-laden vacuoles with electron dense nanostructures and widespread mitochondrial death (Figure 3). Gadolinium-rich precipitates rim these lipid-laden deposits in mouse renal proximal tubule (Figure 4). Di Gregorio et al showed that erythrocytes and leukocytes can retain gadolinium, challenging the previously held notion that GBCA remained mostly in the extracellular space (37). These results indicate GBCAs may exert biological effects not yet understood.
**Renal Function and the Safety of Gadolinium-based Contrast Agents**

Renal function determines the clearance rate of GBCAs and ultimately the safety of their use. It is reflected by glomerular filtration rate (GFR as measured by the urinary clearance rate of a non-protein bound, exogenously administered agent such as inulin which is not secreted or metabolized by the kidneys. These GFR measurements are often laborious and difficult, leading to the use of endogenous biomarkers such as creatinine to derive an estimated GFR (eGFR). Creatinine-based eGFR calculations use equations that include variables such as age, sex and race. Creatinine is secreted by the renal tubules, so its clearance may over-estimate true GFR. Creatinine-based equations were developed using a small number of study patients and it is well-known that they do not apply to all patients generally (38-40). Estimated GFR is an artificial approximation of actual renal function which may not correlate well with true renal function if the patient characteristics do not fit those of the population from which the equations are derived. If these assumptions false, erroneous conclusions of safety will be drawn. It is also fallacious to assume that rapid clearance of GBCA, i.e. rapid removal from the body, ensures safety since the biodistribution of these agents appear more complex than previously believed. The use of dialysis to remove GBCA after exposure to prevent NSF was not always effective, demonstrating that removal alone is insufficient to prevent disease. Administration recommendations based on eGFR should take into consideration these inherent limitations.

**New guidelines: limitations, misinterpretations and our perspective**
Collective clinical experience with GBCA in MRI spans more than 30 years since their introduction. MRI use occurs more in the diagnosis, treatment and monitoring of central nervous system diseases and cancer. However, not all MRI studies require enhancement and unnecessary GBCA exposure may occur. When GBCA use is needed for diagnosis and treatment, the risk of adverse outcomes should be seriously weighed against potential benefits. The American College of Radiology guidelines for GBCA administration advises against administration of group I and group III agents in those on dialysis or with CKD stage 4 or 5 to avoid potential NSF development.

However, the same guidelines also state that the risk of NSF with group II agents “is sufficiently low or possibly nonexistent such that assessment of renal function with a questionnaire or laboratory testing is optional prior to intravenous administration.” Clinicians should be aware that although NSF has not been associated with group II agents in CKD stage 4 or 5 and end stage renal disease, the studies which support this conclusion are limited by their retrospective nature, underpowering and limited dose exposure. Practitioners may erroneously misinterpret these guidelines to mean absolute safety with group II GBCA.

The recommendations based on eGFR carry intrinsic limitations because these estimates are calculated using endogenous biomarkers such as creatinine and cystatin with numerous factors limiting their accuracy (38). The use of eGFR may lead to overestimation of true renal function, mistaken conclusions about GBCA safety and unnecessary use without true clinical benefit, endangering patient safety.

Clinicians who rely on estimations to approximate renal function may not realize their patients lack the same characteristics as the study population from which these
equations are derived, rendering these estimates invalid. We suggest the following considerations: 1) When using any equations to estimate GFR, the clinician must know and understand the patient characteristics and clinical conditions from which these equations are derived. 2) The clinician must determine whether his patient is similar to the study population to determine the validity and applicability of these calculations. If the patient does not fit the study population, then these estimates are invalid and the clinician should seek more accurate measurements. We should not harbor illusions about eGFR safety thresholds since our clinical data have shown these assumptions to be unreliable.

The discovery of NSF and newer findings of brain gadolinium deposition reflect ongoing experience with GBCAs and scientific theories should evolve as new evidence emerges challenging long-held assumptions. Our clinical thought process should also become more sophisticated as new information becomes available. Although brain gadolinium deposition has no objective adverse clinical effects so far, its long-term clinical significance remains uncertain and it is premature to assume lack of harm. Observed brain gadolinium retention with repeated exposure to GBCA administration in those with normal renal function should spur caution and re-examination of current practice patterns. In particular, informed consent should be standard for all stages of CKD when administering these agents since patients should know the long-term risk to their health in their decision making. Deposition disease may be an unanticipated outcome, therefore its risk should be fully disclosed and treated no differently than disclosure of potential adverse effects of other medical treatments. Although we currently cannot state a numerical value of risk, it does not mean we can ignore the
patient’s right to know. The use of dialysis to remove GBCAs to mitigate harm has not proven effective in NSF, and should not be employed to prevent deposition disease. Dialysis, an invasive procedure with its own morbidity and risks, should not be gratuitously applied to remedy a problem preventable with careful thought and consideration.

We advise clinicians to do the following to improve patient safety: 1) Limit the volume of administered GBCA when used, 2) increase patient education, incorporate informed consent and shared decision making when GBCA administration occurs; 3) maintain careful institutional records of administered agents along with the volume and frequency, and 4) employ institutional outcome review and follow up for gadolinium deposition in those receiving multiple doses.

Conclusion

Gadolinium-based contrast agent use has grown since their introduction more than 30 years ago. While GBCAs have played an important role in MRI enhancement necessary for disease detection, their use is not without risk and the long-term biological and clinical effects remain to be seen. Their safety record has been challenged with the finding of NSF and deposition disease, therefore caution and careful deliberation are essential when considering their use. The clinical evidence so far suggests there is no renal function at which GBCA use is absolutely safe and risk free. For those patients needing repeat MRI with potential for multiple GBCA exposures, their risk of deposition disease and NSF may increase with cumulative dose. Clinicians should understand the limitations of estimated GFR in approximating true renal function before assuming low
risk of gadolinium-related diseases. Informed consent should become standard with GBCA administration along with detailed records of type of GBCA, dose and frequency of administration. Careful maintenance of records and clinical outcomes should be employed to improve patient safety. Clinicians should exert discretion when ordering MRI with gadolinium enhancement since it may not confer greater clinical utility but may expose patients to unnecessary risk. As GBCA gatekeepers, they bear the ultimate responsibility for iatrogenic complications.

Figure 1A. Current prevailing pathogenesis theory of nephrogenic systemic fibrosis. Patients with renal impairment or on dialysis are exposed to gadolinium-based contrast agent with retention of these agents due to low renal function. Gadolinium is liberated with decreased clearance leading to tissue deposition and ultimately triggering fibrosis resulting in nephrogenic systemic fibrosis. B. Gadolinium deposition disease pathogenesis theory is less clear. Most notable are recurrent exposures to GBCA in those with normal renal function and its association to brain deposition of gadolinium, but mechanism is unclear.
Figure 2. Gadolinium-based contrast agents induce renal glomerular changes. It has been demonstrated that gadolinium-based contrast agent treatment induces hypercholesterolemia, hypertriglyceridemia, insulin resistance and the Warburg effect in renal cortex [34]. A. Renal cortex from contrast-treated animals demonstrated lipid-like droplets. Scanning electron microscopy (Zeiss Sigma 300 field emission scanning electron microscopy of formalin/glutaraldehyde-fixed tissue, osmicated—1 for 1 h). B. Electron densities in the glomeruli of contrast-treated mice. High electron densities (magenta arrows) occurred intracellularly and in the subepithelial basement membrane. C, D. High magnification imaging
demonstrates that these nanostructures have a spiculated, sea urchin-like appearance previously reported in skin [20]. Transmission electron microscopy, Hitachi HT7700 with AMT 16-megapixel digital camera. Herein, fixed sections of 80 nm thickness were stained with osmium for the transmission electron microscopy images obtained with the Hitachi HT7700.

**Figure 3**

**A.** Invariably, treatment with gadolinium-based contrast agent leads to a peppering of the electron-dense nanostructures in lipid-laden vacuoles of proximal tubular cells. The low magnification transmission electron photomicrograph demonstrates active tubular damage.

**B** The magnified view highlights the lipid-laden vacuoles (cyan arrows), and widespread mitochondrial death (magenta arrows).

**C.** The electron-dense nanostructure precipitates contain gadolinium, phosphorus, and calcium. Sections (200 µm thick, epoxy-embedded) were analyzed by
scanning transmission electron microscopy equipped with energy-dispersive x-ray spectroscopy. Spectra for the electron-dense precipitates ($n = 13$) and renal cortex from an untreated animal ($n = 6$ measurements) were normalized. Areas under the curves compared using William Sealy Gosset’s two-tailed t-tests. JEOL 2010F FEGSTEM operating at 200 kV with Oxford Analytical Aztec energy-dispersive X-ray spectroscopy system, equipped with a XMax 80N 80 mm$^2$ silicon drift detector.
