Abstract

Interstitial inflammation is an important feature of cystic kidney disease. Renal macrophages are the most well studied inflammatory cell in the kidney and their involvement in cyst formation has been reported in different animal models and patients with cystic kidney disease. Originally it was believed that renal macrophages were maintained from a constant supply of bone marrow-derived circulating monocytes and could be recruited to the kidney in response to local inflammation. However, this idea has been challenged using fate mapping methods by showing that at least two distinct developmental origins of macrophages are present in the adult mouse kidney. The first type, termed infiltrating macrophages, are recruited from circulating monocytes and gradually develop macrophage properties upon entering the kidney. The second type of macrophage, termed resident macrophages, predominantly originate from embryonic precursors, colonize the kidney during its development, and proliferate in situ to maintain their population throughout adulthood. Infiltrating and resident macrophages work together to maintain homeostasis and to properly respond to pathological conditions, such as acute kidney injury, cystic kidney disease, or infection. This review will briefly summarize current knowledge of resident macrophages in cystic kidney disease.
1. Macrophages in kidney

Renal macrophages, as the largest population of immune cells in kidney, play a critical role in homeostasis, surveillance, immune response, tissue injury, and repair (1-3). Macrophages are a major constituent of the renal mononuclear phagocyte system and were believed to arise from bone marrow-derived monocytes that could be polarized into different phenotypic subsets in response to environmental stimuli (4-6). However, they were often confused with dendritic cells due to their shared cell surface expression of CD11c and MHCII (7, 8). With the advent of new lineage tracing and single cell RNA sequencing (sc-RNAseq) approaches, it is now possible to clearly delineate macrophages and dendritic cells in the kidney across mammalian species (9-11). In these studies, the authors demonstrated that renal macrophages were highly heterogenous and specialized populations and that they were derived from two different developmental origins (12-14) (Fig. 1). One macrophage type, termed infiltrating macrophages, are derived from monocyte precursors in the bone-marrow and are recruited to the kidney in response to local inflammation (15, 16). The other type, termed resident macrophages, maintain long-term residency in kidney with less mobility and arise primarily during organogenesis (17). They are derived in a \textit{Myb}-independent manner from erythro-myeloid progenitors that are first generated in the fetal yolk sac, colonize the fetal liver, and migrate into the kidney during early development (12, 13, 17).

The idea that resident macrophages are a homogenous population in the kidney and are exclusively derived from embryonic precursors has recently been challenged as well. Utilizing a newly generated \textit{cre}-induced-hCD59 transgenic line, Liu and colleagues traced the fate of resident macrophages in the kidney from birth to full maturity and found that a portion of resident macrophages are actually derived from peripheral monocytes (18). The idea that some kidney resident macrophages are derived from monocytes was supported by data from \textit{Ms4a3}^\textit{Cre}-\textit{Rosa}^{TdT} fate-mapping mice that faithfully label all adult hematopoietic stem cell (HSC) derived monocytes (19). In these studies, the authors showed that a significant portion of kidney resident macrophages were originated from adult HSC derived monocytes. Liu and colleagues also demonstrated that both lineages of resident macrophages shared the feature of long-lived residency in the kidney, but had functional differences in aspects including immune response and metabolic profile in disease conditions (18). These data suggest that kidney resident macrophages can be derived from multiple precursor populations and that their ontological origin may influence their function (6, 17, 18).

In the mouse, infiltrating and resident macrophages can be distinguished based on the expression of surface markers F4/80 and CD11b with resident macrophages being F4/80\textit{high}, CD11b\textit{low} and infiltrating macrophages being F4/80\textit{low}, CD11b\textit{high} (12, 13, 20). The exact function of resident macrophages in the kidney is not well known although emerging evidence suggests that they play an important role in kidney development, vascularization, along with renal repair in response to acute kidney injury (AKI) (17, 21-24). While there is limited data on the function of resident macrophages in the kidney, in part due to the non-specific approaches used to study these cells in the past, we may be able to gain insight into their proposed functions due to similarities between M2-like macrophages and resident macrophages. M2 macrophages have an
anti-inflammatory and pro-fibrotic function (3, 4, 25); most resident macrophages also exhibit an M2-like phenotype with intrinsic anti-inflammatory properties (3). In addition, renal resident macrophages share expression of CD206 and Arg1 with M2 macrophages (20, 26) suggesting that M2 macrophages and resident macrophages are similar populations of cells. It has also been reported that CD206+ M2 macrophages can promote tubular regeneration by expressing growth factors during the reparative phase after AKI, which is similar to the function of resident macrophages in AKI (27-29). While these cells share significant functional properties, direct evidence that M2 macrophages and resident macrophages are the same cell type is still lacking.

Overall, it is evident that the renal macrophage niche in the kidney is more diverse than originally appreciated. To better understand the role of macrophages in kidney under normal and pathological conditions, further studies are needed to characterize the respective functions of these macrophage subsets and the underlying molecular mechanisms involved.

2. Macrophages in cystic kidney disease

Seminal studies in the field of cystic kidney disease highlighted an association between the number of renal macrophages and the severity of cystic disease (30-33). However, it was debated whether macrophages had a causative role in cyst formation or were a secondary consequence of cyst progression and expansion. Karihaloo and colleagues provided the first evidence that macrophages could promote cyst progression in animal models utilizing a phagocytic poison, liposomal clodronate (LC), to deplete all macrophages in the kidney (34). The authors showed that treatment of cystic mice with LC not only significantly decreased the number of renal macrophages (95% reduction), but more importantly, reduced the cystic index and improved renal function when compared to vehicle treated controls (Table 1). The conclusion that macrophages could promote cystic kidney disease was further supported by subsequent studies from Swenson-Fields and colleagues (35). In these studies, the authors showed that treatment with LC also reduced cystic disease in a recessive model of cystic kidney disease. These data suggested that macrophages may be involved in promoting cyst progression in multiple forms of cystic kidney disease. However, since these studies removed all phagocytic cells in the kidney, which includes infiltrating macrophages, resident macrophages, and dendritic cells, the contribution of each subset to cyst progression was still unknown.

There was a long-held belief that renal macrophages are derived from, and are continually replenished by, circulating monocytes. This has led to the idea that targeting the recruitment of monocytes to the kidney may be therapeutically beneficial in the context of cystic kidney disease. This hypothesis is supported by data indicating that genetic deletion or pharmacological inhibition of Ccl2 (also known as monocyte chemoattractant-1 or MCP-1) and macrophage migration inhibitory factor (MIF) reduce the severity of cystic kidney disease (36-38). More importantly, the level of cyst reduction using macrophage-targeted therapeutics was comparable to other inhibitors commonly used in the PKD field such as Tolvaptan or rapamycin (39, 40). While several studies indicate that inhibition of these macrophage ligand: receptor interactions restricts cyst growth, other studies did not report similar findings (41-43). The
involvement of infiltrating macrophages in cystic disease remains controversial and has been reviewed previously (44-47). For comparison we include a table that summarizes the outcomes from multiple studies targeting macrophages in cyst severity (Table 1).

### 3. Resident macrophage involvement in cystic kidney disease

In retrospect, data suggested the presence and involvement of resident macrophages in cystic kidney disease for several decades. For example, multiple studies indicate that alternatively activated M2-like macrophages expressing CD206 (26, 35, 48), a newly identified cross-species marker of resident macrophages (11, 49), could promote renal cyst formation. Microarray analysis from Mrug and colleagues found that in a non-orthologous model of autosomal recessive polycystic kidney disease ($Cys\text{tr}^{cpk/cpk}$), the most highly expressed genes were those associated with the innate immune response (50). Of interest, several of these innate immune genes were recently identified as being specific for resident macrophages by single-cell RNA sequencing ($C1qa, Cxcl16$) (11). Also, Viau and colleagues found increased numbers of both infiltrating and resident macrophages during cyst progression in inducible $Lkb1$ and $Pkd1$ mouse models (36). Although the authors emphasized the importance of infiltrating macrophages in controlling cyst progression in this study, they also observed an increased number of resident macrophages expressing CCR2 (receptor for MCP-1) in cystic kidneys suggesting that the MCP1-CCR2 axis may also be important for resident macrophages.

Zimmerman and colleagues provided evidence for the involvement of resident macrophages in cystic disease using conditional $Ift88$ cilia mutant mice (20). These mutants develop a cystic kidney disease phenotype where the severity is greatly influenced by the age at which cilia loss is induced (51). $Ift88$ loss induced in juvenile periods (prior to postnatal day 14) leads to rapid and severe cyst formation. In contrast, induction in adults results in slow cyst progression occurring in focal regions of the kidney. The rate of cyst formation in adult-induced mutants was found to be greatly increased and more widespread following ischemia-reperfusion injury (IRI). In correlation with these rates of cystogenesis, the authors showed that resident macrophages in wild-type mouse kidneys undergo a phenotypic switch (from CD11c$^{\text{low}}$ to CD11c$^{\text{high}}$) during the postnatal period. CD11c$^{\text{low}}$ resident macrophages are enriched during juvenile periods, negligible in adult mice, and reappeared after renal IRI in adult cilia mutant mice. More importantly, the number of CD11c$^{\text{low}}$ resident macrophages were increased prior to and during cyst formation suggesting a potential causative or at least contributing role for these cells in cyst formation. Analysis of confocal images indicated that most resident macrophages co-expressed F4/80, Ki67, and CD206 in cystic regions, suggesting a reciprocal communication between resident macrophages and cyst-lining epithelial cells (Fig. 2). To understand the mechanism through which resident macrophages were accumulating, the authors performed parabiosis experiments by joining the circulation of a CD45.2 control or cilia mutant mouse with a congeneric CD45.1 wild-type mouse and found that the accumulation of resident macrophages in cilia mutant kidneys was independent of peripheral blood input. Analysis of cell proliferation using Ki67 indicated that accumulation of resident macrophages in injured cilia mutant mice was largely driven by self-proliferation. To
determine the cell type that was responsible for driving resident macrophage proliferation, the authors flow sorted epithelial populations and showed that the expression of membrane-bound colony stimulation factor 1 (mbCSF-1) was significantly increased in proximal tubule cells of the injured cilia mutant kidneys compared with injured controls (Fig. 2). Inhibition of CSF1R kinase signaling, using GW2580, reduced resident macrophage proliferation, prevented the accumulation of CD11c\textsuperscript{low} resident macrophages, and reduced the severity of cystic disease in the injured conditional \textit{ift88} model as well as in the more rapidly progressing \textit{cpk} mouse model. Interestingly, GW2580 treatment did not impact infiltrating macrophage number suggesting that the effects of GW2580 were resident macrophage specific.

Data showing that resident macrophages could promote cystic disease were supported by follow-up studies investigating the involvement of macrophage subsets in an orthologous mouse model of autosomal dominant polycystic kidney disease (ADPKD) (53). Using conditional \textit{Pkd1} mice with unilateral nephrectomy (UNX), Zimmerman and colleagues showed that the numbers of infiltrating and resident macrophages were increased in conditional \textit{Pkd1} mice with UNX compared to sham operated mice and that the increase occurred prior to the onset of severe cystogenesis. Furthermore, the authors showed that interferon regulatory factor 5 (\textit{Irf5}), a transcription factor known to induce inflammatory cytokine production in macrophages (54), was increased in infiltrating and resident macrophages in cystic kidneys. To identify the function of IRF5 in macrophages and its importance in cyst formation, the authors suppressed the expression of IRF5 with an antisense oligo (ASO) treatment and found that IRF5 suppression decreased the number of kidney resident macrophages, reduced inflammatory gene expression, and reduced cyst growth. More careful characterization of infiltrating and resident macrophages showed that IRF5 ASO treatment specifically reduced \textit{Irf5} and \textit{Il6} expression in resident macrophages but did not affect their expression in infiltrating macrophages. More importantly, the authors found that IRF5 ASO-treated mice have reduced STAT3 phosphorylation and expression of p-STAT3 target genes compared to vehicle treated mice suggesting that IRF5-expressing resident macrophages released inflammatory cytokines (IL-6) stimulating STAT3 phosphorylation in the epithelium thereby promoting cyst growth in mice lacking \textit{Pkd1}.

The data presented in this review suggest the involvement of resident macrophages in cystic kidney disease. However, the exact mechanism by which resident macrophages influence cyst growth is largely unknown. Although Zimmerman and colleagues provided evidence that cytokines like IL6 may influence cyst growth through a STAT-dependent mechanism, other direct or indirect mechanisms are likely involved in regulating cyst formation and disease progression (55) (Fig. 2). For example, resident macrophages control injury and repair processes in the kidney by promoting tubular epithelial cell proliferation and de-differentiation, which are hallmarks of renal cyst formation (55). RNA sequencing of resident macrophages after AKI indicated transcriptional reprogramming of resident macrophages, including upregulation of several Wnt genes (\textit{Wnt4}, \textit{Wnt7b}, \textit{Wnt10a}, and \textit{Wnt10b}) (21). Wnt-induced β-catenin signaling can protect against epithelial apoptosis and promote proliferative repair (27, 56, 57). In addition, Wnt signaling can also drive interstitial myofibroblast activation and proliferation, leading to increased matrix protein deposition and renal fibrosis (56, 58).
These data suggest that resident macrophage-derived Wnts promote the proliferation of cystic epithelium and drive interstitial fibrosis during cystic disease progression.

It is also possible that resident macrophages serve as “first responders” in the kidney and control the accumulation and effector function of other immune cells, like neutrophils, infiltrating macrophages, and T cells; cells that have all been observed in patients and mouse models of cystic kidney disease (47, 59-62). In fact, resident macrophages are well suited for this role as they are able to maintain a persistent residence in an adult kidney through self-proliferation and are located directly adjacent to the tubular epithelium (63). Thus, they may serve as sentinels in the kidney to regulate the accumulation of other immune cells that influence cyst growth and progression. Indeed, due to their residency advantage, resident macrophages can act more rapidly than neutrophils, which have always been regarded as first responders in kidney injury. Using a combination of intravital imaging and confocal multiplex microscopy, Uderhardt and colleagues observed that resident macrophages exert a ‘cloaking’ behavior by extending pseudopods around a local injury, which will prevent injury-induced neutrophil activation and neutrophil-driven inflammation (24). Thus, it is possible that resident macrophages serve a similar role in cystic disease.

In addition, epithelial apoptosis is detected during cyst formation (64) and macrophages are known to be professional phagocytes. Thus, resident macrophages may control cyst growth through phagocytosis of damaged epithelial cells and subsequent activation of inflammatory signaling pathways. This is supported by data showing that resident macrophage can detect and scavenge immune complexes or foreign debris in the interstitium and upregulate several inflammatory signaling pathways including NF-κB and JAK/STAT, both of which are associated with worsened cystic disease (22, 65).

Moreover, resident macrophages could also contribute to cyst progression through other mechanisms including regulation of vasculature abnormalities through their proposed pro-angiogenic functions (23, 66, 67). It is also possible that resident macrophages directly or indirectly regulate fluid secretion as data suggest that macrophage-derived cytokines mediate the localization and activity of multiple ion channels in kidney and other tissues (68-71). All of these processes have been reported to be involved in cystic kidney disease (72, 73).

4. Targeting resident macrophages as a potential therapeutic intervention.

Inhibition or reduction of resident macrophage number has beneficial effects both on cyst burden and disease progression in multiple pre-clinical models (20, 53). However, since the mechanism of resident macrophage involvement in cyst growth is unknown, and the approaches for identifying these cells across species are difficult, there have been significant limitations in targeting these cells in patients with cystic kidney disease. Despite these limitations, it should be noted that inhibition of two pro-inflammatory signaling pathways that are present in resident macrophages, the nuclear factor NF-κB and JAK/STAT pathway, has significantly ameliorated cystic severity in animal models (45, 46). For example, a STAT3 inhibitor, S3I-201, significantly inhibited cyst formation and growth in a neonatal PKD mouse model (74). In addition, triptolide has well-known anti-inflammatory effects through inhibiting NF-κB transactivation and its
beneficial effect on cystogenesis in ADPKD mouse models has been reported for decades (75, 76). Results from a phase 3 clinical trial of triptolide in ADPKD (NCT02115659) are much-anticipated (https://clinicaltrials.gov/ct2/show/NCT02115659).

Another caveat to understanding resident macrophage involvement is the difficulty of translating resident macrophage-focused animal studies to the human. This difficulty is due to the fact that markers used to delineate mouse macrophages (i.e. F4/80) are not expressed by their human counterparts, making it challenging to identify analogous populations between species. Also, due to the lack of an appropriate method, there is no way to distinguish monocyte derived infiltrating macrophages from embryonically seeded resident macrophages in the human kidney. Utilizing the recently developed single-cell RNA sequencing technique, Zimmerman and colleagues identified a cross-species kidney resident macrophage–specific gene expression signature by sequencing CD45+ cells isolated from mouse, rat, pig, and human kidney tissue (11). As part of this signature, the authors identified C1QC, CD81, and CD74 as novel, cross species markers of resident macrophages. The authors went on to show that these markers were expressed in mouse resident macrophages at the protein level, and were also co-expressed at the protein level in a population of CD45+ cells isolated from rats and humans. Thus, it is likely that resident macrophages are present in other species and that C1q, CD81, and CD74 can be used to identify these cells.

The identification of resident macrophages in human kidneys will greatly facilitate clinically relevant translational research from murine models to human patient. Macrophage targeting as a potential therapeutic intervention has been implicated and has led to promising results in preclinical models of inflammatory diseases and cancer (77). However, specifically targeting resident macrophages in the kidney of patients is extremely challenging due to the lack of precise approaches to deplete kidney resident macrophages from their useful counterparts in other tissues. Thus, any resident macrophage inhibitors would deplete resident macrophages in all tissues where they are essential for basic biological functions such as synapse pruning, cardiac electrical conduction, and preventing infections (78, 79). Therefore, it is critical to develop kidney specific approaches to selectively deplete resident macrophages.

5. Conclusion and Future perspectives

In summary, studies have shown the involvement of renal resident macrophages in cyst progression and that targeting resident macrophages using genetic deletion or pharmacologic inhibition is a promising therapeutic target for reducing cyst growth. Understating the function of resident macrophages in physiological as well as pathological conditions is important to reveal their mechanism of action in cystic kidney disease and translate these novel mechanisms to benefit patients with cystic kidney disease.

Table 1: Impact of macrophage interventions on cystic kidney disease and their outcomes
Figure Legends:

Figure 1: The origins of macrophages in kidney.
Two types of macrophages are present in the adult mouse kidney. Resident macrophages predominantly originate from embryonic precursors, migrate into the kidney during early development, and are maintained in the kidney through local proliferation. Infiltrating macrophages are derived from monocyte precursors in the bone-marrow and are recruited to the kidney in response to local inflammation. The dashed arrow indicates a limited but continuous contribution of monocyte-derived cells to the resident macrophage pool in adult mouse kidneys.

Figure 2: Proposed functions of resident macrophages during cyst formation and expansion.
Multiple processes occur during cyst formation and expansion including increased epithelial proliferation and apoptosis, interstitial inflammation, increased extracellular matrix deposition and renal fibrosis, as well as vasculature abnormalities. Resident macrophages may be involved in controlling several of these processes directly or indirectly. It has been proposed that resident macrophages can promote cystic epithelial proliferation by secretion of cytokines and phagocytosis of apoptotic epithelial cells. Also, renal resident macrophages may drive interstitial myofibroblast activation and proliferation, leading to increased extracellular matrix deposition and renal fibrosis. Resident macrophages may serve as “first responders” in the kidney and control the accumulation and effector function of other immune cells, like neutrophils, infiltrating macrophages, and T cells, to indirectly regulate cyst formation. Finally, renal resident macrophages may also regulate vasculature abnormalities through their proposed pro-angiogenic functions. The inset indicates the reciprocal communication between resident macrophages and the cilia mutant epithelium via mb-CSF1/CSF-1R.
